#### Abstract

Diabetic patients are more susceptible to cutaneous fungal infections. Cutaneous lesions and Foot infections are a frequent complication of patients with diabetes mellitus, accounting for up to 20% of diabetes-related hospital admissions. Foot ulcers and other foot problems are a major cause of morbidity and mortality in people with Diabetes mellitus. The higher blood sugar levels cause increasing the cutaneous fungal infections in these patients. More than 75% of diabetes mellitus (DM) patients are at risk for diabetic ulcers. About 15% of foot ulcers in diabetic patients lead to amputations. Although every 30 seconds one leg is amputated in the world due to DM, 80% of these cases are preventable. Poor controlled had significantly higher fungal infection in diabetic foot ulcers and require careful attention and management. The findings of various studies indicate that the prevalence of fungal infections in patients with diabetic foot ulcers is increasing and there are many drug resistance issues reported in this area, therefore more attention is important in diabetic centers about this neglected issue.

**Keywords:** Diabetic foot ulcer, Fungal infections, Diabetes mellitus (DM)

#### Introduction

Diabetes mellitus (DM) is the most common endocrine metabolic disease (1). The prevalence of diabetes mellitus in Iran has been reported 7–17% and is increasing in most populations (2, 3). Among persons diagnosed as having diabetes mellitus, the prevalence of foot ulcers is 4% to 10%, the annual population-based incidence is 1.0%

to 4.1%, and the lifetime incidence may be as high as 25% (4).

Type 2 diabetes (T2D) is more common than type 1 diabetes (T1D). The predisposing factors, high blood glucose, vascular insufficiency, neuropathy and, various immunological disturbances, facilitate conditions for colonization of

Pathogenic fungi; including *Candida*, *Dermatophytes*, *Malassezia*, *Zygomycetes*, *Aspergillus* and *Fusarium* species in DM patients (4-6). Nearly 56% of diabetic foot ulcers become infected and 20% of these patients with infected foot ulcers land up in some type of foot amputation. Infections in diabetic foot ulcer are mostly polymicrobial, and risk of development of diabetic foot syndrome is more with mycotic infections. However, little data are available on the prevalence of fungal foot infections in patients with diabetes. The fungi involved in diabetic foot ulcers are mainly *Candida* spp. Other species commonly isolated are *Trichophyton* sp. and *Epidermophyton floccosum* (*E. floccosum*) (7).

Invasive fungal infections are major medical complications in immunocompromised patients. Although aspergillosis and candidiasis are among the most common invasive mycoses in such patients, there is evidence that the incidence of infectious diseases caused by *Zygomycetes* has risen significantly over the past decade. Zygomycosis is a term used to describe a group of fungal infections caused by pathogenic molds belonging to the class *Zygomycetes* of the phylum *Zygomycota*. Zygomycosis is no longer an uncommon disease, due in part to the continued rise of diabetes and the increased use of immunosuppressive agents in the current era of advanced modern medicine. The most common species causing angio-invasive zygomycosis is *Rhizopus arrhizus (oryzae)*, followed by *Rhizopus microsporus* var. *rhizopodiformis* and *Rhizomucor pusillus*. Approximately half of all zygomycosis cases are caused by *Rhizopus* spp. *R. oryzae* is the most frequent cause of rhino-cerebral forms of zygomycosis, whereas *R. microsporus* var. *rhizopodiformis* produces primarily cutaneous and gastrointestinal zygomycosis. *Absidia (Lichtheimia) corymbifera* is the primary species isolated from the earliest case reports of zygomycosis and ranks as the second most

common organism causing zygomycosis. Diabetic patients with sustained hyperglycemia, particularly those with ketoacidosis, are more susceptible to zygomycosis. In fact, diabetes mellitus as a predisposing factor has been reported in 36–88% of all zygomycosis cases (8). Therefore, screening and early detection of fungal infections in high-risk individuals are critical for prevention of grave complications like foot amputation. In some diabetic patients, developing cutaneous lesions, and nail infections have been documented (9). More than 75% of DM patients are at risk for diabetic ulcers. A diabetic foot ulcer is one of the most important complications in diabetic patients. About 15% of foot ulcers in diabetic patients lead to amputations. Although every 30 seconds one leg is amputated in the world due to DM, 80% of these cases are preventable (10). The foot lesions are often chronic and resistant to treatment. These ulcers are prone to secondary infections; bacterial, fungal and viral (11). Poor controlled had the significantly higher fungal infection in diabetic foot ulcers and require careful attention and management (12). Persons with DM have a 15% to 25% chance of developing a diabetic foot ulcer (DFU) during their lifetime, and a 50% to 70% recurrence rate over the ensuing 5 years. More than half of persons with diabetes mellitus are unaware of their disease. 2.5% to 15% of annual global health care budgets are spent on diabetes mellitus. Diabetes mellitus is the seventh leading cause of death in the United States. Diabetes mellitus is the leading cause of kidney failure, non-traumatic lower extremity amputations, and new cases of blindness in adult Americans. Diabetic foot ulcers are often preventable, and treatment is frequently suboptimal. Chronic wounds, including DFUs, are a common yet challenging problem. Diabetic foot ulcers precede 85% of lower limb amputations. Diabetic foot ulcers are the most expensive and preventable complication of diabetes

mellitus. The average lower limb amputation and rehabilitation cost \$44,790. Persons with DM are susceptible to peripheral neuropathy with sensory, autonomic, and motor components. Neuropathy is one of the main contributory factors in the pathogenesis of DFUs. Micro- and macro-vascular disease in persons with DM may impair healing of the ulcers and is critically important. Ischemia has been reported as a contributing factor in 90% of diabetic patients undergoing major amputation. Increased plantar pressure resulting from neuropathy is the major risk factor for diabetic foot ulcers. Neuropathy impairs the ability to perceive injury because of a loss of protective sensation. Autonomic neuropathy involves the sympathetic nervous system and presents as anhidrosis with dry skin and fissures that needs to be distinguished from other causes of dry plantar skin. These changes must be distinguished from a fungal infection because the fourth and fifth web spaces are common areas for fungal intertrigo while the plantar surface and the sides of the foot are common areas for a moccasin distribution. Diabetic foot ulcers can be divided into neuropathic, ischemic, and neuro-ischemic foot ulcers, with the latter 2 having a less favorable prognosis (13).

Fungal infections are usually neglected aspects of cutaneous lesions in DM patients. Foot infections are a frequent complication of patients with diabetes mellitus, accounting for up to 20% of diabetes-related hospital admissions. Bacteria are predominant in acute diabetic foot infections and that chronic infections may involve gram-negative bacteria and anaerobes. Recent South Indian studies have shown that gram-negative bacteria in diabetic foot ulcers are mostly mono-microbial (14).

Our findings indicated more than 80% of patients with diabetic foot ulcers had a history of trauma and burns and more than 50% of them had neuropathic ulcers. In Seattle, 46% of the amputations were related to ischemia, 59% to infection, 61%

to neuropathy, 81% to faulty wound healing, 84% to ulceration, 55% to gangrene and 81% to initial minor trauma (15). Trauma and burns with an impaired leucocyte functions in diabetic patients could be the risk factors for the high prevalence of fungal infection at the recent studies (16-18).

Literature data on the frequency of fungal infection on the different type of cutaneous lesions is significantly different. Gupta et al showed that diabetic patients with onychomycosis were more at risk for diabetic ulcers and gangrene (12.2%) than normal individuals with onychomycosis (19). *C. albicans* is the most common yeast isolated from the diabetic foot ulcer, skin and nail lesions and *A. flavus* was the most prominent causative agent of onychomycosis in DM patients in Isfahan (3). Over the past several decades, the incidence of nosocomial fungal infections (i.e., invasive fungal infections acquired in a healthcare-associated setting) has dramatically increased. The relative frequencies with which fungi cause nosocomial infections are inversely related to the intensity of immunosuppression required to predispose to them. For example, relatively minimal immunosuppression is required to predispose to invasive *Candida* infections, and *Candida* is by far the most common cause of nosocomial fungal infections. *Aspergillus* is the second most frequent cause of nosocomial fungal infections and aspergillosis tends to occur in patients with an intermediate to severe degree of immunocompromise. Finally, organisms such as the Mucorales, *Fusarium*, and other molds (e.g., *Scedosporium*) are relatively less common, and are seen virtually exclusively in the most severely immunocompromised hosts, and in hosts that are compromised for prolonged periods of time (20). Fungal infections of urinary tract infections are commonly caused by *Candida* spp and rarely present as “fungus ball.” Unusual organisms and gram-negative pathogens other than “*E coli*” may

also occur in patients with diabetes mellitus. Patients with diabetes mellitus are at increased risk of superficial fungal infections like onychomycosis and tinea pedis. Mucormycosis is an uncommon, acutely fatal fungal infection that predominantly affects immunocompromised patients. It carries a high mortality ranging from 15% to 34%. Rhinocerebral mucormycosis, the most common form of infection, predominantly affects patients with poorly controlled diabetes, especially with diabetic ketoacidosis. Patients with rhinocerebral mucormycosis with concomitant diagnosis of diabetes ranged from 60% to 81%. Infections in diabetic patients result in extended hospital stays and additional financial burden(21).

Dorko et al, in a study on DM patients in Slovakia, found that, *C. albicans* was the most frequent yeast in patients with

onychomycosis followed by *C. parapsilosis* (22).

### Conclusion

The findings of various studies showed a high prevalence of fungal infection in diabetic and diabetic foot ulcer patients and *C. albicans* was the prominent fungus isolated from these patients. Wise consideration of the possibility of fungal infections, early recognition, and appropriate treatment ensure rapid healing and eliminate amputation risk, minimize mortality and costs.

### Acknowledgments

Sincere gratitude of all professors and students of mycology at the School of Public Health in Tehran University of Medical Sciences.
